Economic equilibrium and optimization problems using GAMS
Notes 6: general equilibrium with distortionary taxes, public goods, infrastructure, pollution externalities

James R. Markusen
University of Colorado, Boulder

Taxes in the benchmark equilibrium

A positive tax and tax revenue are present in the benchmark data.
The first task: construct a micro-consistent data set. Remember that entries are values.

Each tax should be added as a row to the matrix.

Taxes are negative entries in a column indicating payments by a sector.
There is a corresponding positive entry somewhere. In the present case, the tax is redistributed lump sum to the consumer, so the consumer gets a positive entry of the tax revenue.

A zero row sum for the tax indicates that all tax receipts must be paid to someone.

</tbody>
</table>
X sector receives 100 units of revenue, of which 20 is paid in taxes.

This 20 is received as part of the consumer’s income.

These data do not indicate what type of tax is in place. It could be a tax on X output, on all the inputs, or on just one input. We interpret this as a tax on the labor input into sector X.

A crucial task: keep track of what prices firms and consumers face. It is (generally) not possible to calibrate a benchmark equilibrium with all prices equal to one.

If a production input is taxed, then if its consumer price (price received by the consumer) is chosen to be equal to one, then producer price (price paid by the producer) is specified as \((1 + t)\).

If the producer price is unity, the consumer price is \(1/(1+t)\).
Given that we interpret the above data as a tax on the labor input into the X sector, the data tell us that the tax rate is 100%.

The amount paid by the X sector to labor (20) is equal to the tax revenue (20).

Thus if we set the consumer price of labor to 1 (also the price to the Y sector), then the price of labor to the X sector must be 2.

Allow for alternative taxes in the model, including a tax on capital inputs into X (TKX) and a tax on X output (TX), set to zero initially.

\[
100 \times (1 + TLX) \times PL/2 \times 0.4 \times (PK \times (1 + TKX)) \times 0.6 = G = 100 \times PX \times (1 - TX) ;
\]
Counterfactual: eliminate taxes on X sector inputs and replace with a single tax on X sector output. Then taxes on both inputs.

The output tax rate will be different from the corresponding tax rate on all inputs, because the tax base is different in the two cases.

Let $mc$ denote the marginal cost of production (or producer price) and $p$ denote the price charged to the consumer. This is how MPS/GE interprets input ($ti$) versus output ($to$) taxes.

Tax on all inputs: $p = (1 + ti)mc$
Tax on the output: $p(1 - to) = mc$

Note $mc$ is the tax base for the input tax, and $p$ is the tax base for the output tax. The output tax that is equivalent to the tax on all inputs is found by:

$$(1 + ti) = 1/(1 - to)$$
If $ti = TLX = TKX = 0.25$ as we have assumed in our first counterfactual, then the equivalent output tax is given by $to = TX = 0.20$.

One more equivalence: The final counterfactual demonstrates that a 20% tax on the output of X is the same as a 25% subsidy to the production of Y.

Let $t$ be the tax on X and $s$ the subsidy to Y. Formally, we have

$$\frac{p_x(1 - t)}{p_y} = \frac{p_x}{p_y(1 + s)} = \frac{mc_x}{mc_y} \quad \text{if} \quad t = 0.20, \quad s = 0.25$$

Absolute prices may differ depending on the choice of the numeraire, but all quantities and welfare are the same.

6.2a Labor supply and labor tax

This model is an extension of the previous model and also extends our earlier model with endogenous labor supply (M3-6) to a case with taxes in the benchmark.

There are supply activities for labor (TL) and capital (TK). Labor can also be used for leisure and so the activity level for labor supply will vary.

Capital has no alternative use so it will always be completely supplied to the market.

Still, it can be convenient to specify a supply activity, since there will be two prices, one the consumer price and one the producer price (user cost) of capital.

Our choice will be that the consumer prices (prices received by the consumer) for labor and capital will be set to one.

The data matrix indicates that there is a 50% tax on each factor in the benchmark, so the producer prices (user costs) of labor and capital will be $PLS = PKS = 1.5$. 
We can also choose how to interpret the X and Y values, but there is only a single price for both producers and consumers, so we will interpret these as 120 units at a price of 1 for each.

One useful trick for checking the calibration and noting which sectors or markets are out of balance is to not allow the model to iterate initially.

```
PLS.L =1.5; PKS.L =1.5;
INCOMETAX.ITERLIM = 0;
SOLVE INCOMETAX USING MCP;

M32.ITERLIM = 2000;
SOLVE INCOMETAX USING MCP;
```
Suppose that we had set the initial value of PLS.L = 1.0 instead of 1.5. Look at the listing file.

The model has not solved. Recall from chapter 1 that GAMS writes inequalities in the greater-than-or-equal-to format.

The MARGINAL column of the listing file gives the degree of imbalance in an inequality, left-hand side minus right-hand side.

A positive number is ok if the associated variable is zero, as in a cost equation (marginal cost minus price is positive if associated with a slack activity).

A negative value of a marginal cannot be an equilibrium; for an activity it indicates positive profits and for a market it indicates demand exceeds supply.

In our incorrect calibration in which we give the producer price of labor too low a value, we see that there are positive profits for X, Y and negative profits for labor supply. There is an excess demand for labor and an excess supply for capital.
Most calibration errors are in the MPS/GE file itself, and not just in setting the initial values of the variables.

You could work with this file as an exercise, deliberately introducing errors (such as in the price fields) and see what happens. In any case, the iterlim = 0 statement is very useful in helping you identify where the errors are.

The other useful feature we introduce in this model is the use of the LOOP statement to simplify the repeated solving of the model over a series of parameter values. Two parameters are declared as vectors, WELFARE(S), and LABSUP(S) (for labor supply).

Then the loop statement sets the taxes at different values over the values of the set.
LOOP(S,

TXL = 0.60 - 0.10*ORD(S);
TXK = 0.40 + 0.10*ORD(S);

SOLVE ALGEBRAIC USING MCP;

WELFARE(S) = W.L;
LABSUP(S) = TL.L;
INCOME(S) = ((PX.L/1.5)*X.L + (PY.L/1.5)*Y.L)
           /((PX.L/1.5)**0.5*(PY.L/1.5)**0.5)/2;
CAPTAX(S) = TXK;
TAXREV(S) = (TXL*PL.L*TL.L*80 + TXK*PK.L*TK.L*80)
           /((PX.L/1.5)**0.5*(PY.L/1.5)**0.5);
);

DISPLAY WELFARE, LABSUP, INCOME, CAPTAX, TAXREV;
ORD(S) denotes the ordinal value of a member of a set. S is an indicator and is not treated as a number in GAMS, so 0.05*S won’t work.

ORD(S) is treated as a number, so this is how the set index is translated into a number. Note from the tax assignment statement that when S = 1, the initial values of both taxes are 0.20, our benchmark values. At S = 5, the values are TXL = 0, and TXK = 0.40.

The model is repeatedly solved within the loop, and after each solve statement the value of the parameters WELFARE and LABSUP are assigned values. The loop is closed with “ ); ”

After the loop is closed we ask GAMS to display the parameters at the end of the listing file. Note the set index for the parameters is not used in the display statement, GAMS knows what it is.

6.2b Equal yield tax reform

We set up a model in which we can do differential tax policy analysis holding the level of government revenue constant.

This model introduces a fourth (and final) class of variables (in addition to activity levels, commodity prices and income levels).

The new entity is called an "auxiliary variable". In this model, we use an auxiliary variable to endogenously alter the tax rate in order to maintain an equal yield.

In the present case, we will hold the labor tax rate *exogenous*, but change its value, solving for the value of the *endogenous* capital tax that yields the same value of revenue as the original tax.

TXK now become a *variable*, not a *parameter*. 
In the initial statements specifying the variables and the equations the model, we declare an extra variable TXK and an extra equation A_TXK (“A” for auxiliary)

Here is the constraint equation as it appears in the model

\[
\text{A_TXK.. TXL*PL*TL*80 + TXK*PK*TK*80 =E= 80 * (PX**0.5 * PY**0.5)};
\]

The left-hand side is tax revenue from the two taxes, one an exogenous parameter (TXL) and the other an endogenous variable (TXK).

Each term is (tax rate) \* (factor price) \* (activity level for factor supply) \* (the reference quantity supplied at an activity level equal to one).
The right-hand side of the constraint specifies the target revenue. The modeler has to think carefully about what is meant by “constant” revenue: that is, constant in terms of what?

Assume that the government wants the taxes to yield an amount equal to the cost of purchasing a “composite” unit of (sub) utility from X and Y. The cost is given from the consumer’s expenditure function as

\[ 80 \times ((P_X^{0.5} \times P_Y^{0.5}) \];

Of course, the government is not actually buying anything in this simple model, it is just redistributing the revenue back to the consumer.

But the modeler must specify what the revenue target is in real terms.
In our case, the initial value of $TXK = 0.50$, so we set this along with the values of $PLS$ and $PKS$ which are equal to 1.5 initially, along with the initial value of the parameter $TXL$ (the latter is a parameter and so does not use the ‘.L’ syntax).

```plaintext
PX.L = 1.;
PY.L = 1.;
PLS.L = 1.5;
PKS.L = 1.5;
TXL   = 0.50;
TXK.L = 0.50;
```

After the replication check, we loop over values of $TXL$, and each solve statement finds the new value of $TXK$ as one variable in the new general-equilibrium solution.

In each iteration, we store the values of key variables so that they can be presented together at the end of the listing file.
We include the difference between the effects of the reform on real commodity consumption (REALCONS) and true welfare (WELFARE), the latter accounting the value of leisure.

Note from the results in the present case, that measuring only the change in real commodity consumption significantly overstates the true welfare gain of the tax reform (which is tiny) because of the fall in leisure (increase in labor supply).

6.3 Public consumption goods

The assumption of lump-sum redistribution is a convenient trick which simplifies tax policy analysis.

In practice, governments often use money to purchase things which private markets cannot provide..

In this model, we first explicitly introduce government as an agent or “consumer” (GOVT).

The tax revenue collected in the economy is assigned to the government.

The government spends this on purchasing a good called G (price PG), produced from capital and labor like goods X and Y.

</table>

The government is the only agent demanding PG in the model and taxes are the government’s only source of income.
Each consumer receives the full benefit of the public good: a public good is non-rivaled.

And a consumer cannot be charged for the good, nor can a consumer sell it to other consumers: a public good is non-excludable.

The way that we do this in GAMS is to have the government buy the good from tax revenue, then the full amount of the good is transferred or endowed to each consumer.

This is done via an auxiliary variable and a constraint equation.

\[ \text{LGP} = \text{G} \]

where G is production of the good and LGP is each consumer’s endowment of the good, viewed as exogenous.
Since each consumer’s endowment of the good is fixed and equal, consumers with different incomes or preferences will in general have different demand prices for the good.

These are often referred to as “willingness to pay”.

PG1 and PG2 are the demand prices or willingness to pay by consumers 1 and 2 respectively.

These are in effect separate or “personalized” goods: one consumer cannot sell his/her good to the other consumer.

We can capture the non-excludability and non-rivaled properties by thinking of two separate “markets”: each consumer “demands” the good they are endowment with which, because the quantity is fixed, allows us to solve for each consumer’s demand price separately.
Here are the relevant, key equations, where again, LGP is viewed as exogenously by each consumer.

\begin{align*}
\text{MKT\_G1} &.. \ 50\times\text{LGP} \ = G = 50 \times W1 \times PW1\times0.5/PG1; \\
\text{MKT\_G2} &.. \ 50\times\text{LGP} \ = G = 50 \times W2 \times PW2\times0.5/PG2; \\
\text{I\_CONS1} &.. \ \text{CONS1} = E = 50\times\text{PL} + 50\times\text{PK} + 50\times\text{LGP}\times\text{PG1}; \\
\text{I\_CONS2} &.. \ \text{CONS2} = E = 50\times\text{PL} + 50\times\text{PK} + 50\times\text{LGP}\times\text{PG2}; \\
\end{align*}

**Optimality:** the optimal provision of a public good occurs when the marginal cost of providing the good equals the sum of the consumers’ willingness to pay (since equal consumer gets the full benefit of an additional unit: non-rivaled).
In the data, we have assumed that the valuations of the public goods at a price \( PG1 = PG2 = 0.5 \) and the marginal cost of provision is \( PG = 1 \).

Thus the initial data represent an optimal initial provision of the public good. \( PG = PG1 + PG2 \).

Note that this is an assumption. We do not actually observe the demand prices (willingness to pay) in any real data.

(A big task in environmental economies is to estimate willingness to pay for various goods; e.g., parks and open space.)

6.4 Optimal provision using a Samuelson rule

This model is exactly the same as the previous one, except that the tax used to finance the public good is endogenous.

Instead of TAX being a parameter, it is now an auxiliary variable. Its value is set by the constraint equation:

\[ PG = PG_1 + PG_2; \]

Since each consumer gets the full amount of the public good (the good is “non-rivaled”), the marginal benefit of another unit of the good is the sum of the demand prices for all the consumers.

Efficiency is achieved when this sum of benefits is equal to the marginal cost of producing another unit.
Note that the auxiliary variable itself need not appear in the constraint equation associated with it. The solution algorithm will adjust TAX in order to satisfy this condition.

Caveat: the Samuelson rule is valid only if the tax needed to pay for the public good can be raised in a non-distortionary way.

If distortionary taxes must be used, the sum of marginal benefits must be weighed against the marginal cost of production plus the marginal burden of taxation.

When we run this model, we will get back a value of TAX = 0.25, because we calibrated the preferences assuming that the initial data was optimal.
As a counterfactual experiment, we change one consumer’s valuation of the public good, by changing the share parameters in consumer 1's utility function.

Share parameters in the benchmark are set and declared as:

PARAMETERS
  SHX1, SHY1, SHG1  shares of X Y and G in 1's utility
  SHX2, SHY2, SHG2  shares of X Y and G in 2's utility;

SHG1 = 0.2;
SHX1 = 0.5 - SHG1/2;
SHY1 = 0.5 - SHG1/2;
SHG2 = 0.2;
SHX2 = 0.5 - SHG2/2;
SHY2 = 0.5 - SHG2/2;
Counterfactual experiment sets:

\[
\begin{align*}
\text{SHG1} &= 0.3; \\
\text{SHX1} &= 0.5 - \text{SHG1}/2; \\
\text{SHY1} &= 0.5 - \text{SHG1}/2;
\end{align*}
\]

Note that, although the higher tax is efficient according to the Samuelson rule, it nevertheless results in a redistribution of welfare from the low valuation consumer to the high valuation consumer.

6.5 Public intermediate (infrastructure) good with optimal provision

Suppose that output in the X sector is given by

\[ X = \alpha L, \]

where \( L \) is a private input and \( \alpha \) is a parameter which is increasing in the level of a government-provided infra-structure good.

Individual firms view \( \alpha \) as exogenous.

Producing one unit of \( X \) then requires \( 1/\alpha \) units of \( L \). The unit cost function for \( X \) is then \( p_l/\alpha = p_x \).
The public good G is produced from labor only (the only factor of production), and is financed by an equal tax on all goods (including the public good).

The equation for alpha is given by

\[ \text{ALPHA} = 1 + \text{INFPROD} \times G; \]

where INFPROD is a parameter giving productivity of G in X.

The marginal product of G in producing X (L held constant), is then

\[ \frac{\partial X}{\partial G} = \text{INFPROD} \times L \]

where L is the labor used in X.
Referring back to the production function, we can replace $L$ with

$$\frac{\partial X}{\partial G} = \text{INFPROD} \cdot \left(\frac{X}{\alpha}\right)$$

Now multiply this by $P_X$ to get the value of the marginal product of $G$ in $X$. This should then be set equal to the price (marginal cost) of a unit of $G$, $P_G$.

$$p_g = p_x \cdot \text{INFPROD} \cdot \left(\frac{X}{\alpha}\right)$$

This will be an auxiliary equation that sets a non-distortionary (endogenous) income tax rate $T_X$ to its optimal value.

6.6a Pollution from production affects utility

This model is: two goods, one factor, one consumer

Pollution is generated by the production of X, pollution reduces utility

Pollution is modeled as a reduction in the endowment of CLEAN AIR

Initial endowment of clear air is 200, with 100 reduced by X pollution and 100 entering utility. PCA = price of clean air.

</tbody>
</table>
As in the case of a public good, this public “bad” must be modeled as non-rivaled and non-excludable. (Non-rivaled is trivial here since there is only one consumer.)

The utility function gives 1/3 equal weights to X, Y, and CA. Expenditure function is given by:

\[
PRF_W = 200 \times (PX^{1/3} \times PY^{1/3} \times PCA^{1/3}) = G = 200 \times PW;
\]

Shepard’s lemma then gives a demand for clean air: as in the public good case, consumer’s cannot actually chose;

Rather, this gives a demand price for the given amount of clean air. This “willingness to pay” is part of the solution to the model.
The supply of clean air is given as the endowment 200, minus that which is “stolen” by pollution from the production of X: 100*POL.

\[
\text{MKT\_CA.. } 200 - 100\times \text{POL} = G = 100 \times W \times PW / PCA;
\]

Consumer income will be defined as inclusive of the value of clean air, similar to our treatment of leisure. TX is a pollution tax on X.

\[
\text{I\_CONS.. } \text{CONS} = E = 200\times PL + (200 - 100\times \text{POL})\times PCA + TX\times 100\times X\times PL;
\]

Pollution is proportional to the production of X. POLINT is a parameter for pollution intensity of X production.

\[
\text{PPOL.. } 100\times \text{POL} = G = \text{POLINT}\times 100\times X;
\]

6.6b Uses MPEC to solve for the optimal pollution tax

Now we make TX a variable rather than a tax. Second, we introduce another (unbounded) variable WELFARE (to be optimized). WELFARE just equals W from M6-6a.

This is an MPEC (optimization problem subject to equilibrium constraints). There is no need for an added equation for the added variable TX. The solver will find its optimal value.

The model has one unmatched equation (WELFARE), with the constraint set the same general-equilibrium model of M6-6a.

TX is not matched to an equation.

6.6c  Optimal tax set by a Pigouvian tax formula

Another way to find the optimal tax is to use a Pigouvian tax rule, which states that the price of the polluting good must equal its full cost.

In our case, this is the price of the privates inputs (labor) needed to produce one unit of $X$ plus the marginal damages of pollution from one more unit of $X$.

So now we add an equation (and drop WELFARE) which is matched to the variable $TX$. This is given by:

\[
\text{ATX..} \quad PX = E = PL + PCA*POLINT;
\]

or noting that $PX = PL*(1 + TX)$, the equation can be written as:

\[
\text{ATX..} \quad TX = E = PCA*POLINT/PL;
\]
$TITLE M6-6c.GMS: Pollution tax set optimally via a
* "first-order condition"

6.7 Two households with different preferences, endowments

This model is an adaptation of model M3-7:

Here we introduce a social welfare function and find taxes that maximize social welfare.

This is modeled as an MPEC. Model M3-7 is the constraint set on the MPEC.

The model allows for variable (and endogenous) weights on each household type in social welfare. This model can be viewed as a basic starting point for thinking about political economy.
Two household: differ in preferences and in endowments

Household A: well endowed with labor, preference for labor-int good Y
Household B: well endowed with capital, preference for capital-int good X

Allows for tax to be redistributed unevenly between households, and for a lump-sum redistribution for comparison purposes.

The tax redistribution or sharing rule can also be interpreted as the relative number of households in each group, with all households getting an equal share of tax receipts.

Parameters

- WEIGHTA  weight of consumer A in social welfare
- WEIGHTB  weight of consumer B in social welfare

Variables

- SHA  share of tax redistributed to consumer A
- SHB  share of tax redistributed to consumer B
- LS  lump sum redistribution to consumer A;
Add a variable, social welfare \( WS \), and an equation giving the social welfare function.

\[
\text{OBJ..} \quad \text{WS} = E = (\text{WA}^{\text{WEIGHTA}}) \times (\text{WB}^{\text{WEIGHTB}});
\]

The income-balance constraints for the two consumer types reflect their redistributive shares of total tax revenue, and/or lump-sum redistribution.

\[
\text{I_CONSA..} \quad \text{CONSA} = E = 90 \times \text{PL} + 10 \times \text{PK} + \\
\quad \text{SHA} \times \text{TAX} \times 100 \times \text{X} \times \frac{\text{PX}}{(1+\text{TAX})} + \text{LS};
\]

\[
\text{I_CONSB..} \quad \text{CONSB} = E = 10 \times \text{PL} + 90 \times \text{PK} + \\
\quad \text{SHB} \times \text{TAX} \times 100 \times \text{X} \times \frac{\text{PX}}{(1+\text{TAX})} - \text{LS};
\]

To make the problem interesting, we (initially) have a single tax instrument, and production/consumption tax on \( X \).
Thus the only available tax is distortionary and creates an aggregate welfare loss. There is a cost to redistributing income.

Note that the optimal tax might be a subsidy, so the variable TAX is specified as a free (unbounded) variable.

The model is calibrated so that, if the welfare weights on the two consumer groups are equal, the optimal tax is zero.

Now give a higher weight to households A: WEIGHTA = 0.7.

Perhaps 70% of all households by count (and votes) are type A
A higher weight on households A, will mean a positive tax for two reinforcing reasons:

Good X is capital intensive
   And

Households B are capital abundant
   And

Households B have a high preference for X in consumption

Thus a positive tax hurts households B and helps households A.
Experiment 1: maximize welfare holding shares SHA and SHB fixed at 0.5, and fixing LS at 0: no lump-sum transfers possible.

Experiment 2: maximize welfare allowing for endogenous shares

Experiment 3: maximize welfare allowing for lump-sum transfers

Experiment 4: reverse the weights on the two household types
adaptation of model M3-7: distortionary tax can be used for redistribution modeled as an MPEC: find the optimal tax maximizing social welfare two add-ons (1) allows the redistributive shares of tax revenue to be endogenous (2) allows an optimal lump-sum redistribution for comparison

Two household: differ in preferences and in endowments
Household A: well endowed with labor, preference for labor-int good Y
Household B: well endowed with capital, preference for capital-int good X

The tax redistribution or sharing rule can also be interpreted as the relative number of households in each group, with all households getting an equal share of tax receipts.

PARAMETERS

WEIGHTA  weight of consumer A in social welfare
WEIGHTB  weight of consumer B in social welfare;

WEIGHTA = 0.5;
WEIGHTB = 0.5;

VARIABLES

WS  social welfare
TAX  endogenous tax rate on X
LS  lump sum redistribution;

NONNEGATIVE VARIABLES

X  Activity level for sector X,
Y  Activity level for sector Y,
WA  Activity level for welfare for consumer A
WB  Activity level for welfare for consumer B
PX  Price index for commodity X,
PY      Price index for commodity Y,
PK      Price index for primary factor K,
PL      Price index for primary factor L,
PWA     Price index for welfare A (expenditure function),
PWB     Price index for welfare B (expenditure function),

CONSA   Income definition for CONSA,
CONSB   Income definition for CONSB

SHA     share of tax redistributed to consumer A
SHB     share of tax redistributed to consumer B;

EQUATIONS

OBJ      Social welfare function
PRF_X    Zero profit for sector X
PRF_Y    Zero profit for sector Y
PRF_WA   Zero profit for sector WA (Hicksian welfare index)
PRF_WB   Zero profit for sector WB (Hicksian welfare index)

MKT_X    Supply-demand balance for commodity X
MKT_Y    Supply-demand balance for commodity Y
MKT_L    Supply-demand balance for primary factor L
MKT_K    Supply-demand balance for primary factor K
MKT_WA   Supply-demand balance for aggregate demand consumer A
MKT_WB   Supply-demand balance for aggregate demand consumer B
I_CONSA  Income definition for CONSA
I_CONSB  Income definition for CONSB
ADDUP   Sum of the redistributive shares equals 1;

*  Objective function (social welfare function) to be maximized

OBJ..       WS =E= (WA**WEIGHTA) * (WB**WEIGHTB);

*  Zero profit conditions:

PRF_X..   100 * (PL**0.25 * PK**0.75) * (1+TAX) =E= 100 * PX;
PRF_Y..   100 * (PL**0.75 * PK**0.25) =E= 100 * PY;
PRF_WA..   100 * PX**0.4 * PY**0.6 =E= 100 * PWA;
PRF_WB..   100 * PX**0.6 * PY**0.4 =E= 100 * PWB;

*  Market clearing conditions:

MKT_X..   100 * X =E= 40*WA*PWA/PX + 60*WB*PWB/PX;
MKT_Y..   100 * Y =E= 60*WA*PWA/PY + 40*WB*PWB/PY;
MKT_WA..   100 * WA =E= CONSA / PWA;
MKT_WB..  100 * WB =E= CONSB / PWB;
MKT_L..   90 + 10 =E= 25*X*(PX/(1+TAX))/PL + 75*Y*PY/PL;
MKT_K..   10 + 90 =E= 75*X*(PX/(1+TAX))/PK + 25*Y*PY/PK;

*       Income constraints:
I_CONSA.. CONSA =E= 90*PL + 10*PK + SHA*TAX*100*X*PX/(1+TAX) + LS;
I_CONSB.. CONSB =E= 10*PL + 90*PK + SHB*TAX*100*X*PX/(1+TAX) - LS;
ADDUP..   SHA + SHB =E= 1;
